Varieties of Currency Crises

The plethora of currency crises around the world has fueled many theories on the causes of speculative attacks. The first-generation models focus on fiscal problems. The second-generation models emphasize countercyclical policies and self-fulfilling crises. In the 1990s, models pinpoint to financial excesses. With the crisis of Argentina in 2001, models of sovereign default have become popular again. While the theoretical literature has emphasized variety, the empirical literature has supported the “one size fits all” models. This paper contributes to the empirical literature by assessing whether the crises of the last thirty years are of different varieties. Crises are found to be of six varieties. Four of those varieties are associated with domestic economic fragility. But crises can also be provoked by just adverse world market conditions, such as the reversal of international capital flows. The so-called sudden-stop phenomenon identifies the fifth variety of crises. Finally, a small number of crises occur in economies with immaculate fundamentals but this type of crises is not an emerging-market phenomenon.

1. INTRODUCTION

The plethora of financial crises that have ravaged emerging markets and mature economies since the 1970s has triggered a variety of theories on the causes of speculative attacks. Models are even catalogued into three generations. The first-generation models focus on the fiscal and monetary causes of crises. These models were mostly developed to explain the crises in Latin America in the 1960s and 1970s. The second-generation models aim at explaining the EMS crises of the early 1990s. Here the focus is mostly on the effects of countercyclical policies in mature economies and on self-fulfilling crises, with rumors unrelated to market fundamentals at the core of the crises. The next wave of currency crises, the Tequila crisis in 1994 and the so-called Asian Flu in 1997, fueled a new variety of models — also known as third-generation models, which focus on moral hazard and imperfect information. The emphasis here has been on “excessive” booms and busts in international lending and asset price bubbles. With
the crisis in Argentina in 2001, academics and economists at international institutions are now dusting off the articles of the 1980s modeling crises of default.

The abundance of theoretical models has failed to generate the same variety of empirical models. Most of the previous empirical research groups together indicators capturing fiscal and monetary imbalances, economic slowdown, and the so-called over-borrowing syndrome to predict crises.\footnote{See, for example, Berg and Patillo (1999), Eichengreen, Rose, and Wyplosz (1995), Frankel and Rose (1999), Kaminsky (1998), and Sachs, Tornell, and Velasco (1996).}

While this research has certainly helped to capture the economic fragility at the onset of crises and therefore to predict balance of payment problems, it has failed to identify the changing nature of crises and to predict those crises that do not fit a particular mold. This paper contributes to this literature by assessing whether the crises of the last thirty years are of different varieties. As a by-product, this paper contributes to the early warning literature by providing new forecasts of the onset of financial crises.

To identify the various classes of crises, I examine crisis episodes for twenty industrial and developing countries. The former include: Denmark, Finland, Norway, Spain, and Sweden. The latter focus on: Argentina, Bolivia, Brazil, Chile, Colombia, Indonesia, Israel, Malaysia, Mexico, Peru, the Philippines, Thailand, Turkey, Uruguay, and Venezuela. The period covered starts in January 1970 and includes crises up to February 2002, with a total of ninety-six currency crises. To gauge whether crises are all of the same nature or whether groups of crises show unique features, I use a variety of macroeconomic and financial indicators suggested by the previous literature — totaling eighteen variables — and a multiple-regime variant of the signals approach.\footnote{See Kaminsky (1998) and Kaminsky and Reinhart (1999) for an application of the one-regime signals approach to forecasting crises.}

Once crises are classified, I examine whether the nature of crises varies across emerging and mature economies and tally the degree of severity of each type of crisis.

The key finding is that, in fact, crises have not been created equal. Crises are found to be of six varieties. Four of those varieties are associated with domestic economic fragility, with vulnerabilities related to current account deterioration, fiscal imbalances, financial excesses, or foreign debt unsustainability. But crises can also be provoked by just adverse world market conditions, such as the reversal of international capital flows. The so-called sudden-stop phenomenon identifies the fifth variety of crises. Finally, as emphasized by the second-generation models, crises also happen in economies with immaculate fundamentals. Thus, the last variety of crises is labeled self-fulfilling crises.

The second finding is that crises in emerging markets are of a different nature than those in mature markets. Crises triggered exclusively by ad-
verse shocks in international capital markets and crises in economies with immaculate fundamentals are found to be a mature-market phenomenon. In contrast, crises in emerging economies are triggered by multiple vulnerabilities.

The last finding concerns the degree of severity of crises. As it is conventional in the literature, severity is measured by output losses following the crises, the magnitude of the reserve losses of the central bank, and the depreciation of the domestic currency. I also estimate a variety of measures capturing the extent of borrowing constraints/lack of access to international capital markets following crises. Notably, the degree of severity of crises is closely linked to the type of crises, with crises of financial excesses scoring worst in this respect.

The rest of the paper is organized as follows. Section 2 reviews the literature on crises and examines the particular symptoms associated with each model. Section 3 examines the multiple-regime signals approach. Section 4 is the main part of the paper and examines the characteristics of crises in the twenty countries in the sample. The section pays particular attention to the types of crises that have afflicted mature and emerging markets. It also tallies the severity of the various classes of crises. Section 5 examines the early warnings of crises implicit in this approach. Section 6 concludes.

2. MODELS OF CURRENCY CRISSES

The earlier models of balance of payments problems were inspired by the Latin American style of currency crises of the late 1960s and early 1970s. In these models, unsustainable money-financed fiscal deficits lead to a persistent loss of international reserves and ultimately ignite a currency crash (See, for example, Krugman, 1979 and Lahiri and Végh, 2003). Stimulated by the EMS collapses in 1992 and 1993, more recent models of currency crises have stressed that the depletion of international reserves might not be at the root of currency crises. Instead, these models focus on government officials’ concern on, for example, unemployment. Governments are modeled facing two often conflicting targets: reducing inflation and keeping economic activity close to a given target. Fixed exchange rates may help in achieving the first goal but at the cost of a loss of competitiveness and a recession. With sticky prices, devaluations restore competitiveness and help in the elimination of unemployment, thus prompting the authorities to abandon the peg during recessions.3

The crises in Latin America in the 1980s, the Nordic countries in 1992, Mexico in 1994, and Asia in 1997 have prompted the economics profession to model the effects of banking problems on balance-of-payments difficul-

---

3See, for example, Obstfeld (1986), (1994), and (1996).
ties. For example, Diaz Alejandro (1985) and Velasco (1987) model difficulties in the banking sector as giving rise to a balance-of-payments crisis, arguing that if central banks finance the bail-out of troubled financial institutions by printing money, we have the classical story of a currency crash prompted by excessive money creation. Within the same theme, McKinnon and Pill (1994) examine the role of capital flows in an economy with an unregulated banking sector with deposit insurance and moral hazard problems of the banks. Capital inflows in such an environment can lead to over-lending cycles with consumption booms and exaggerated current account deficits. Most of the times, the over-lending cycles are also accompanied by booms in the stock and real estate markets. In turn, the over-borrowing cycles lead to real exchange rate appreciations, losses of competitiveness, and slowdowns in growth. As the economy enters a recession, the excess lending during the boom makes banks more prone to a crisis when a recession unfolds. This state of business becomes even more complicated by the pervasive over-exposure of financial institutions to the stock and real estate markets, which makes banks even more vulnerable when asset bubbles burst as the recession approaches. The deterioration of the current account, in turn, makes investors worried about the possibility of default on foreign loans. In turn, the fragile banking sector makes the task of defending the peg more difficult and may lead to the eventual collapse of the domestic currency. In a similar vein, Goldfajn and Valdés (1995) show how changes in international interest rates and capital inflows are amplified by the intermediation role of banks and how such swings may also produce an exaggerated business cycle that ends in bank runs and financial and currency crashes.

More recently, the literature on capital inflows and capital inflow problems has suggested another potential source of instability (see, for example, Calvo, 1998, Calvo and Reinhart, 2000, and Calvo, Izquierdo, and Talvi, 2002), that of liquidity crises due to sudden reversals in capital flows. For example, the debt crisis in 1982, the Mexican crisis in 1994 and the so-called Tequila effect, and the Asian crisis in 1997-1998 show that capital inflows can come to a sudden stop and even can sharply reverse their course and become capital outflows. As emphasized by those authors, the sudden reversal, prompted, in large part, by fluctuations in interest rates in industrialized countries, is far more persistent and severe when the borrowing country is an emerging economy, highly indebted, dollarized, and with debt concentrated at short-maturities. In these cases, sudden stops trigger massive depreciations of the domestic currency.

The now revitalized literature on sovereign default has been mostly concerned with the ability or the willingness of a country to service the debt. This literature mostly developed in the 1980s following the debt crisis in 1982. In a seminal contribution, Eaton and Gersovitz (1981) argue that
sovereign lending can take place even if borrowers are immune to any direct actions by creditors in the event of no repayment. In this approach, borrowers will not be tempted to default if they are concerned that they will lose their reputation in international credit markets and lose future access to borrowing. In contrast, Cohen and Sachs (1982) assume that if a country fails to make repayments, it will suffer a loss that is proportional to the country’s output, perhaps because creditors can enforce repayment through direct punishments such as disturbing the international trade of any borrower that unilaterally defaults. The literature on sovereign crises has continued to grow, with the empirical research emphasizing that defaults are more likely if the level of debt and the interest rates at which the countries borrow are high or if there are adverse output shocks, such as deterioration in the country’s terms of trade.

3. CAPTURING VARIETIES: METHODOLOGY

The empirical research on predicting currency crises has adopted a variety of econometric techniques. Parametric techniques include probit and VAR models. Non-parametric techniques are mostly confined to the leading-indicator methodology. While currency crises can take many forms, all the estimations impose “the one size fits all” approach, with the indicators predicting crises including indicators related to sovereign defaults, such as high foreign debt levels, or indicators related to fiscal crises, such as government deficits, or even indicators related to crises of excesses, such as stock and real estate market booms and busts. That is, in all cases, researchers impose the same functional form to all observations. When some indicators are not robustly linked to all crises, they tend to be discarded even when they may be of key importance for a subgroup of observations. For example, as examined in Kaminsky and Reinhart (1999), financial market booms and busts are an important trigger of crises after financial liberalization but the deterioration of the current account is at the core of crises before financial liberalization. Naturally, if these non-linearities are known, they can be controlled using interactive terms. Yet, such knowledge is the exception rather than the rule.

Another source of non-linearities impossible to capture in a standard regression framework or signals approach is that crises become more likely as the number of fragilities increases. For example, a real exchange appreciation of a certain magnitude becomes more worrisome if coupled with excessive monetary expansion. Similarly, high foreign debt leads to a further deterioration of the economy if accompanied by high world real interest rates.

In this paper, I will use a different methodology to allow for ex-ante unknown non-linearities. This methodology is a modification of the con-
ventional leading-indicator methodology, which has a long history in the rich literature that evaluates the ability of macroeconomic and financial time series to predict business cycle turning points (see, for instance, Stock and Watson, 1989, and Diebold and Rudebusch, 1989). More recently, this technique has also been applied to predict crises. The basic idea in the leading-indicator methodology is that the economy evolves through phases of booms and recessions or, in our case, of tranquil times and crisis episodes and that some fundamentals start to behave differently at the onset of a recession or a crisis and thus can be used to predict the change in regime. This change in behavior of a particular series is captured empirically by finding a “threshold” that turns a fluctuation of a given variable into a signal of an upcoming recession or crisis. In most of the applications, this threshold is the one that minimizes the noise-to-signal ratio of the particular indicator. In this methodology, the working assumption is that recessions or crises are just of one type. Moreover, thresholds are obtained indicator by indicator without consideration of possible complementarities. In contrast, the proposed new methodology allows the data to determine the number and characteristics of classes of crises. Also, the thresholds that turn a fluctuation of a variable into a signal of an upcoming crisis will be identified jointly for all indicators to allow for interdependence.

To identify the possible multiple varieties of crises, I apply regression tree analysis. This technique allows one to search for an unknown number of sample splits (in our case, varieties of crises and of tranquil times) using multiple indicators. Breiman et al (1984) show that the regression tree method is consistent in the sense that, under suitable regularity conditions, the estimated piecewise linear regression function converges to the best nonlinear predictor of the dependent variable of interest. The actual sorting algorithm is described in Durlauf and Johnson (1995). Intuitively, this methodology behaves as a multiple-regime signal-approach. To identify the types of crises, the observations are first divided into those observations in periods of crises and observations of tranquil times. Crisis times are identified with a 1 while tranquil times are identified with a 0. As in

---

4 Also, booms or “tranquil times” are assumed to be of just one type.  
5 This methodology can be thought of as the non-parametric alternative to the multiple-regime Markov-process models pioneered by Hamilton (1989). However, in contrast to the multiple-regime Markov-process model, the number of regimes does not need to be specified exogenously, it can be determined endogenously.  
6 See Durlauf and Johnson (1995) and Ghosh and Wolf (1998) for applications of the regression tree analysis to characterize multiple regimes in growth behavior.  
7 See Breiman et al (1984) for a description of this technique.  
9 Observations are catalogued into crisis times and tranquil times using an index of exchange market pressure. See Kaminsky and Reinhart (1999) for a detailed explanation on the identification of crises.
the conventional signal approach, the algorithm first chooses thresholds for each indicator to minimize its noise-to-signal ratio.\textsuperscript{10} Then, the indicator with the lowest noise-to-signal ratio is selected. All observations are then separated into two groups: those for which the chosen indicator is signaling and those for which the indicator is not signaling. For each group, the methodology is repeated. Again, for each of the remaining indicators, new thresholds are selected to minimize the noise-to-signal ratio. Note that this time the threshold that converts a fluctuation of an indicator into a signal of an upcoming crisis is conditioned on the selection of the first indicator and its threshold. This allows to find complementarities: even minor fiscal problems can add to fragility and trigger crises if accompanied by vulnerability of the banking sector. In this second round, groups are created based in the classification of the indicator with the lowest noise-to-signal ratio from all remaining indicators.\textsuperscript{11} This process continues, with each new round helping to classify observations into more tightly defined groups. Obviously, this process can continue until each observation is classified into a different type. To avoid the perfect fit, the regression tree analysis imposes a penalty on the number of varieties. As explained in Gosh and Wolf (1998), the rule used resembles an adjusted $R^2$ criterion, with the improvement due to the identification of a new variety being compared with a penalty on the number of varieties. If the penalty exceeds the improvement, the algorithm chooses the previous number of varieties, otherwise the algorithm continues to partition the sample. Still, no asymptotic theory exists to test the statistical significance of the number of regimes uncovered by the regression tree. Finally, it should be noted that the algorithm classifies both crisis episodes and tranquil times.

\textsuperscript{10}The selection of the appropriate threshold that turns the fluctuation in an economic time series into a signal of an upcoming crisis tries to fulfill conflicting criteria. If the threshold is too “lax,” that is, “too close” to normal behavior, it is likely to catch all the crises but it is also likely to catch a lot of crises that never happened, that is, send a lot of false signals. Alternatively, if the threshold is too “tight” it is likely to miss all but the most severe of crises — the price of reducing the number of false signals will be reflected in a lower proportion of crises accurately called. The first step of the multiple-regime signal approach, as the first step of the one-regime signal-approach, selects the “optimal” threshold on an indicator-by-indicator basis by performing a search over all possible thresholds and selecting the value that minimizes the noise-to-signal ratio of each indicator.

\textsuperscript{11}Each indicator can be used several times (with different thresholds) to partition the observations. For example, a 40-percent real appreciation by itself can signal a future crisis. Still, a 10-percent real appreciation can signal a crisis if accompanied by excessive international borrowing.
4. THE ANATOMY OF CURRENCY CRISES

The regression-tree methodology was applied to the data and the results of this exercise are described below. First, the data and the estimated classification are presented. Afterwards, the discussion is organized so as to answer the following questions: What are the varieties of financial crises that we observe in this sample of over 90 crises; and Do these fit a certain mold? Are crises in mature and emerging markets of the same variety? How severe are the consequences of each type of crisis?

4.1. The Data

Following the literature on early warnings, this paper will classify currency crises using information on a variety of indicators. These indicators are described in Table 1. Indicators are grouped according to the symptoms on which the various generation models focus on. The first-generation models of currency crises highlight the inconsistency of expansionary macroeconomic policies with the stability of a fixed exchange rate regime. Fiscal deficits and easy monetary policy are at the core of these models. I capture the spirit of these models with two indicators: fiscal deficit/GDP and excess M1 real balances.\footnote{Excess real money balances are the residuals from a money demand equation. Money demand is estimated as a linear function of output and expected inflation.} The second-generation models focus on countercyclical government policies. The essence of these models is centered on problems in the current account, with real appreciations fueling losses in competitiveness and recessions. I capture the focus of these models with five indicators: Exports, imports, real exchange rate (deviations from equilibrium), terms of trade, output, and real interest rates. The third-generation models focus on financial excesses. To capture the spirit of these models, I use six indicators: domestic credit/GDP ratio, M2/reserves, deposits, M2 multiplier, stock prices, and an index of banking crises. The literature on sovereign crises has focused mainly on too much debt and even debt concentrated at short maturities. To examine this variety of crises, I use two indicators: Foreign debt/exports, and short-term debt/foreign exchange reserves. Finally, the sudden-stop approach focuses on international capital flow reversals, which I will try to capture with fluctuations in both the world real interest rate and foreign exchange reserves of central banks. There are a total of eighteen indicators. The Appendix describes the data in detail.\footnote{Not all real appreciations are a signal of losses in competitiveness, with for example, improvements in productivity in the traded-good sector triggering appreciations in the equilibrium real exchange rate. “Equilibrium” movements of the real exchange rate are captured with a time trend. See, also Goldfajn and Valdez (1996) for a comparison of the ability of various methodologies in capturing equilibrium fluctuations of the real exchange rate.}
To examine the characteristics of crises, the paper looks at a total of twenty countries: Argentina, Bolivia, Brazil, Chile, Colombia, Denmark, Finland, Israel, Indonesia, Malaysia, Mexico, Norway, Peru, Philippines, Spain, Sweden, Thailand, Turkey, Uruguay, and Venezuela. As it is conventional in the crisis literature, crisis months are those months with a large exchange rate pressure index.\textsuperscript{14} The dates of the crises for the twenty countries are reported in Table 2. Ninety-six crises were identified. I

\textsuperscript{14}In the spirit of Eichengreen, Rose, and Wyplosz (1995) and following Kaminsky and Reinhart (1999), the index of currency market turbulence was constructed as a weighted average of exchange rate changes and reserve changes, with weights such that the two components of the index have equal conditional volatilities. Since changes in the exchange rate enter with a positive weight and changes in reserves have a negative weight attached, readings of this index that were three standard deviations or more above the mean were cataloged as crises. With countries in the sample that, at different times, experienced hyperinflation, the construction of the index had to be modified. While a 100-percent devaluation may be traumatic for a country with low-to-moderate inflation, a devaluation of that magnitude is commonplace during hyperinflations. If a single index for the countries that had hyperinflation episodes were constructed, sizable devaluations and reserve losses in the more moderate inflation periods would be left out since the historic mean is distorted by the high-inflation episode. To avoid this problem, the sample was divided according to whether inflation in the previous six months was higher than 150 percent and then constructed an index for each subsample.
should note that when classifying crises, I do not classify just the month of the crisis. The build-up of fragilities preceding a crisis starts early on. Thus, as in Kaminsky and Reinhart (1999), I define “crisis episodes” as the month of the crisis plus the twenty-four months preceding the crisis. Thus, in the sample, there are 2400 observations of crisis episodes and 5280 observations of tranquil times.15

4.2. The Classification

To estimate the types of crisis episodes, the data on all indicators for each country are first transformed into percentiles of the distribution. This transformation allows for idiosyncratic factors since, for example, a monthly 20-percent fall in stock prices can be business as usual in emerging markets but is a strong signal of crisis in a mature economy.

The results of the regression tree are shown in Figure 1. The hexagons show the various criteria for dividing the sample while the squares are the final groups of observations. The tree algorithm classifies all observa-

---

15Since the definition of crisis episodes is ad hoc, Kaminsky and Reinhart (1999) check for robustness of the results. In particular, we also define crisis episodes as the 12-month and the 18-month window prior to crises. We find that all qualitative results remain with the different definitions of crisis episodes.

Sources: Kaminsky & Reinhart, 1999 and updates.

The table presents a chronological list of currency crises in various countries, detailing the months and years of the crises. Only nine indicators are used to catalogue all observations: real exchange rates, exports, excess real M1.
balances, domestic credit/GDP, M2/Reserves, fiscal deficits/GDP, foreign
debt/exports, short-term debt/reserves, and world interest rates.\textsuperscript{16} Interestingly, the first split of the data is based on the real exchange rate,
indicating that real exchange rate appreciations are the most important
signal of a forthcoming crisis, confirming the findings of previous studies
(e.g. Goldfajn and Valdés, 1996, and Frankel and Rose, 1996). Observa-
tions with the real exchange rate at the 17.8 percentile of the distribution or
lower have a 74.3-percent probability of crises. In contrast, a more depre-
ciated real exchange rate signals crises with just a 25.7-percent probability.
For those observations with an appreciated real exchange rate, the group-
s are further defined with classifications based on domestic credit/GDP,
fiscal deficit/GDP, world interest rates, foreign debt/exports, short-term
debt/reserves, and excess M1 real balances. In particular, some observa-
tions are identified by real appreciations, high domestic credit/GDP, high
fiscal deficit/GDP, and high excess M1 real balances. Those observations
are associated with an 82-percent probability of crises. For those observa-
tions with no problems of real appreciation (observations with real exchange
rates higher than the 17.8 percentile), the groups are further defined with
classifications based on the level of world interest rates, fiscal deficits/GDP,
and M2/Reserves ratio. In particular, one variety of crises identified in this
branch is the one studied by the first-generation models. The observations
in this group are characterized by fiscal deficits/GDP in the 3.7 percentile
or lower and are associated with an 87-percent probability of crises.\textsuperscript{17}

Table 3 describes in detail the characteristics of the final groups. The
indicators signaling vulnerability are shown in bold. For example, the
first node is characterized by a real appreciation of the domestic currency
(real exchange rate in the 17.8-percentile or lower), low debt/exports ratio
(debt/exports in the 71.5-percentile or lower), low short-term debt/reserves
(short-term debt/reserves in the 16.6-percentile or lower), and low world
interest rates (world interest rates in the 84.5-percentile or lower). Thus,
the only observed vulnerability in this group is the appreciation of the real
exchange rate, which is shown in bold characters.

Some of these groups share similar traits. For example, the vulnera-
bilities in groups 1 and 2 are only related to the real appreciation of the
domestic currency while the vulnerabilities of groups 14 and 15 are both
associated with hikes in world interest rates. To account for these similari-
\textsuperscript{16}By looking at all the indicators jointly, the regression tree analysis allows to min-
imize the number of indicators needed to classify and predict crises. For example, in
these estimations, the index of economic activity is not selected as a separate indicator.
Economic activity seems to be well captured by some of the chosen indicators, such as
the real exchange rate, domestic credit, and fiscal policy.
\textsuperscript{17}Since fiscal deficits are represented with negative numbers, large fiscal deficits are
located in the left tail of the distribution.
ties. I combine the eighteen groups into six varieties of crises. Ten of those groups are characterized by episodes of real appreciation. For four of them, real appreciations reflect the only shown vulnerability. I catalogue these

Graciela L. Kaminsky

For the other six, the real appreciation is not necessarily the main determinant of crises, it just contributes to the build up of economic fragilities. When the fragilities are associated with booms in financial markets, crises are catalogued as Crises with Current Account Problems.\(^\text{18}\) These crises can also be associated with the second-generation models of currency crises.

4.3. Varieties of Crises in Emerging and Mature Economies

Table 4 shows the classification of the ninety-six crises in the sample into the six varieties on a crisis-by-crisis basis. To classify crises, I look at the episodes of crises (the month of the crisis and the twenty-four preceding months) and using Table 3, I tally the number of months in that particular episode with vulnerabilities arising from the current account, financial of Financial Excesses.\(^{19}\) In particular, they are identified as crises that are preceded by the acceleration in the growth rate of domestic credit and other monetary aggregates. In turn, when the fragilities are associated with “unsustainable” foreign debt, crises are classified as Crises of Sovereign Debt Problems. The fourth variety of crisis is related to expansionary fiscal policy. These crises are labeled Crises with Fiscal Deficits.\(^{20}\) Sudden-Stop Crises constitute the fifth variety of crisis. This type of crisis is associated with reversals in capital flows triggered by hikes in world interest rates.\(^{21}\) Finally, Self-fulfilling Crises are those associated with node 13, which does not exhibit any evident vulnerability. The last column of Table 3 shows the associated probabilities of crises of each node.

---

\(^{19}\)See also, Gourinchas, Landerretche, and Valdés (2002) and Schneider and Tornell (2003) for an analysis of the relationship between booms and busts in credit markets and crises.

\(^{20}\)These crises can also be associated with the first-generation models of currency crises.

\(^{21}\)Guillermo Calvo (1998) introduced the concept of sudden stops in the crisis literature. Sudden stops in this interpretation are associated with a reversal of international capital flows. But hikes in world interest rates or changes in international investors’ sentiments are not the only defining characteristic of sudden stop crises. These crises are also linked to vulnerabilities in borrower countries, which include high levels of debt, dollarization, and debt concentrated at very short maturities. In our classification, sudden stop crises are just associated to one type of vulnerability: severe hikes in world interest rates.

\(^{22}\)For three of these crises, there is no data available on the various indicators. So, only ninety-three crises are classified.
excesses, fiscal deficits, debt problems, or sudden stops. The last column shows the classification for each crisis episode. If all the twenty-five observations in a crisis episode are classified in outcome 13, which shows an economy without vulnerabilities, that episode is classified as a self-fulfilling crisis. Otherwise, as a general rule, a crisis is classified as type \( j \) if the majority of the months of the crisis episode are classified in variety \( j \). So, for example, as shown in Table 4, the collapse of the Turkish Lira in February 2001 is classified as a crisis of financial excesses because there are twenty-two months classified in outcomes 8 and 10.\(^{23}\)

This classification indicates that 14 percent of the crises are related to current account problems, 29 percent are crises of financial excesses, 5 percent are crises with fiscal problems, 42 percent are crises of sovereign debt problems, 5 percent of the crises are related to sudden stops, and just 4 percent of the crises are self-fulfilling crises.

Table 5 shows the varieties of crises in emerging and mature economies.\(^{24}\) As shown in this table, crises in emerging markets tend to be of a different variety than those in mature markets. For example, current account and competitiveness problems are more of a trait of mature markets (17 percent of the crises) than of emerging economies (13 percent of the crises). While it is true that losses of competitiveness also affect emerging economies, lack of competitiveness is just one of the many vulnerabilities that these economies suffer. More often than not, lack of competitiveness is accompanied by highly expansionary credit growth and loose monetary policy or debt problems or even macro-policies inconsistent with the stability of

\(^{23}\)There are three exceptions to the general rule. First, a number of crisis episodes includes some observations classified as observations with current account problems and some other observations classified as observations with financial excesses. Since crises of financial excesses are characterized by excessive expansion of credit/monetary aggregates as well as by real appreciations as in the case of crises with current account problems, I classify those crisis episodes as episodes with financial excesses to show the presence of multiple vulnerabilities. For example, current account problems and financial excesses were widespread during the Mexican crisis of December 1994, with 14 months showing current account problems and nine months showing “financial excesses.” The 1994 Mexican crisis is classified as a crisis of financial excesses even though the number of months with current-account problems exceeds that with financial excesses. Second, some crisis episodes include observations with financial excesses and fiscal problems. Since fiscal problems are part and parcel of debt problems, those crisis episodes are classified as crises with debt problems. Third, some crisis episodes include observations with financial excesses and observations with debt problems. Again, as debt problems are part and parcel of financial excesses, those episodes are classified as crises of financial excesses. A final note, when observations are classified into various groups, the only groups that are considered for the classification of the crisis episode are those that include at least six observations. Since this is an ad-hoc criterion, robustness tests have been performed. Qualitative results are not affected. The results are available upon request.

\(^{24}\)Denmark, Finland, Norway, Spain, and Sweden are the mature economies in the sample. The remaining countries in the sample are considered emerging economies.
the peg. Overall, eighty-six percent of the crises in emerging economies are crises with multiple domestic vulnerabilities while economic fragility
only characterizes 50 percent of the crises in mature markets.\textsuperscript{25} Sudden-stop problems are also more common in mature markets (17 percent of all crises) than in emerging markets (2 percent of all crises). Again, in our classification, sudden-stop problems are just characterized by adverse

\textsuperscript{25}The crises associated with multiple vulnerabilities are Crises of Financial Excesses, Crises of Fiscal Deficits, and Crises of Sovereign Debt problems.
shocks to international capital markets and crises in emerging economies mostly occur in the midst of multiple vulnerabilities. Finally, while most of the crises are preceded by real, financial, or external fragilities, a small number of crises are unrelated to deteriorating fundamentals (Self-fulfilling

</table>

Notes: The top panel shows the percent of crises in each variety. For example, 35 percent of all crises in emerging markets are classified as crises of Financial Excesses.

These crises are not a feature of emerging markets but tend to occur in mature markets.26

Table 6 evaluates the costs of the different varieties of crises. Costs are grouped into three categories. The first one captures the magnitude of the speculative attack. Two indicators are used: losses of reserves and real exchange rate depreciations. For reserves, I use the six-month percentage change prior to the month of the crisis, as losses of reserves tend to occur before the devaluation occurs (if the speculative attack is successful). For the real exchange rate depreciation, I use the six-month percentage real depreciation following the month of the crisis since large devaluations tend to occur only after and if the central bank concedes by devaluing or floating the currency. The second category focuses on output losses (relative to trend) in the year of the crisis and one year after the crisis so as to examine not only the magnitude of the collapse following the crisis but also the persistence of output losses. The third category looks at access to international capital markets in the aftermath of the crisis. It focuses on the behavior of the trade account in the year following the crisis. The table reports separately the 12-month percentage change (relative to trend) in exports and imports following the month of the crisis. The first six columns report the average for each variety of crises. The last column shows the average across all crises.

26While in the theoretical literature self-fulfilling crises are associated with the EM-S crises in 1992 and 1993, the implied classification from the regression tree identifies those episodes as crises with domestic vulnerabilities. In the case of Denmark, Finland, Norway, and Sweden, vulnerabilities are associated with international borrowing and debt problems, while in the case of Spain, fragilities are related to financial excesses. The regression tree only classifies as self-fulfilling crises, or crises with immaculate fundamentals, the crises associated with the collapse of the Bretton Woods System.
VARIETIES OF CURRENCY CRISSES

As shown in Table 6, reserve losses oscillate around 14 percent for all crises with the exception of those classified as self-fulfilling, for which reserves increase about 15 percent in the months preceding the crises. The depreciation of the real exchange rate across type of crises is more varied and oscillates between 1 and 31 percent. Depreciations are most extreme in the case of crises of financial excesses. As is the case with real depreciations, output losses (relative to trend) are also substantially larger in the aftermath of crises of financial excesses. In this case, output losses increase to almost 4 percent. In contrast, output (relative to trend) is unchanged or continues to grow in the aftermath of crises with no observed domestic fragility, both those of the sudden-stop and the self-fulfilling varieties. Output losses are somewhat persistent. On average, during the second year after the crisis, output continues to fall relative to trend. Again, declines in economic activity are less pronounced in the aftermath of crises with no domestic fragility.

Finally, Table 6 also shows that, as discussed in Calvo (1998) and Calvo and Reinhart (2000), access to international capital markets can be severely impaired in the aftermath of crises, with countries having to run sizable current account surpluses to repay their debt. The size and type of the adjustment varies across types of crises. For example, in the case of crises with financial excesses, most of the adjustment occurs on the import side, with imports falling — relative to trend — approximately 25 percent. In con-
contrast, exports fail to grow (deviations from trend growth are almost zero) even though the depreciations during this type of crises are massive. This evidence suggests that countries are even unable to attract trade credits to finance exports when their economies are mired in financial problems. In contrast, for crises with no domestic fragilities, booming exports are at the heart of the recovery of the current account. Summarizing, on average, the costs of crises with financial excesses are significantly higher than those of other crises, with crises of debt problems being a close second. On the opposite end, self-fulfilling crises or crises triggered by just reversal in capital flows have no noticeable adverse effects on the economy.

5. THE EARLY WARNINGS

Figure 2 reports the time-series probabilities of currency crises implicit in the estimation for all countries in the sample for the period January 1970-December 2001. The shaded areas in the figures are “crisis times.” Overall, there are 2400 observations of crises (31 percent) and 5280 observations of “tranquil times” (69 percent). Macroeconomic vulnerabilities are basically not present during “tranquil times,” with 77 percent of the observations being classified under outcome 13. For those observations, the probability of crises is just 13.5 percent. This is the frequency of crises in times of immaculate fundamentals.

In most cases, vulnerabilities are highly persistent and they trigger repeated exchange rate crises. For example, Colombia suffered a series of crises in the late 1990s. Similarly, the July-1997 crisis in Thailand that set the onset of the Asian crisis was followed by a string of crises that only ended in July 2000. Episodes of multiple crises can be of the same nature. This was the case of Argentina in the late 1980s and beginning of the 1990s, with debt problems at the heart of all speculative attacks. In contrast, the nature of the crises in Thailand evolved from problems of excessive borrowing at the beginning of the episode to fiscal problems following the bailout of the banking sector.

This section evaluates the forecasting accuracy of the multiple-regime signals approach vis-à-vis the traditional signals approach (Kaminsky, 1998). I follow Diebold and Rudebusch (1989) in evaluating both techniques. Two tests are implemented to evaluate the average closeness of the predicted probabilities and observed realizations, as measured by a zero-one dummy

---

FIG. 2. Probabilities of Currency Crises

Note: Shaded Areas denote crisis windows

variable. Suppose we have \( T \) probability forecasts:

\[
\{P^k_t\}_{t+1}^T
\]  

where \( P^k_t \) is the probability of crisis conditional on information provided by the indicator \( k \) in period \( t \). Similarly, let

\[
\{R_t\}_{t+1}^T
\]

be the corresponding time series of realizations; \( R_t \) equals one during crisis episodes and zero otherwise. The first scoring-rule is the quadratic probability score, (QPS), given by

\[
QPS^k = \frac{1}{T} \sum_{t=1}^T 2(P^k_t - R_t)^2
\]  

The QPS ranges from 0 to 2, with a score of 0 corresponding to perfect accuracy.

The second scoring-rule is the log probability score (LPS), given by

\[
LPS^k = -\frac{1}{T} \sum_{t=1}^T [(1 - R_t) \ln(1 - P^k_t) + R_t \ln(P^k_t)]
\]
The LPS ranges from 0 to $\infty$, with a score of 0 corresponding to perfect accuracy. The loss function associated with LPS differs from that corresponding to QPS, as large mistakes are penalized more heavily under LPS.

**TABLE 7.**

<td>0.235</td>
<td></td>
</tr>
</tbody>
</table>

Notes: QPS refers to the Quadratic Probability Score and LPS refers to the Log Probability Score.

Table 7 shows both the Quadratic Probability Score (QPS) and the log Probability Score (LPS) for the forecasting probabilities of the two indicators. The score statistics are reported separately for the whole sample, “Crisis Times” and “Tranquil Times.” As shown in this table, the multiple-regime signals approach makes a substantial improvement over the traditional signals approach. This holds regardless of the loss function used. For the whole sample, the losses in forecasting accuracy from using the one-regime signals approach reach 26 percent. Losses in predictive accuracy from using the one-regime signals approach even reach 47 percent during tranquil times, indicating that the multiple-regime signals approach issues substantially less false alarms.

6. CONCLUSIONS

Currency crises are not a new phenomenon. Not only is the list of countries affected by these crises long but it is also increasing. Many have emphasized the destructive forces of currency crises, and the economics profession as a whole is crusading to find ways of avoiding crises. But while some countries collapse following a crisis, many others that also fall prey to speculative attacks do not suffer catastrophic consequences, suggesting that crises come in many varieties. Yet, most previous empirical studies of crises have failed to allow for this diversity.

In this paper, I used regression tree methods to classify ninety-six crises in twenty countries from 1970 to 2001. The results indicate that crises are not created equal, with the empirical classification reflecting the varieties proposed by the various generations of models of currency crises. Still, some models are better than others at capturing the stylized characteristics of crises. For example, I find that most of the crises are characterized by
multitude of weak economic fundamentals, suggesting that it would be difficult to characterize them as “self-fulfilling” crises.

Finally, since crises are of different varieties, early-warning systems should allow for multiple regimes. Thus, the second-generation early-warning systems should incorporate methodologies such as regression tree analysis or parametric multiple-regime models à la Hamilton (1989) to capture a broad spectrum of crises.

APPENDIX: THE INDICATORS: SOURCES AND DEFINITIONS

Sources: International Financial Statistics (IFS), International Monetary Fund (IMF); Emerging Market Indicators, International Finance Corporation (IFC); World Development Indicators, The World Bank (WB); The Maturity, Sectoral, and Nationality Distribution of International Bank Lending, Bank for International Settlements (BIS); International Banking and Financial Market Developments, Bank for International Settlements. When data was missing from these sources, central bank bulletins and other country-specific sources were used as supplements. Unless otherwise noted, all variables are in 12-month percent changes.

1. M2 multiplier: The ratio of M2 (IFS lines 34 plus 35) to base money (IFS line 14).
2. Domestic Credit/GDP: IFS line 52 divided by IFS line 64 to obtain domestic credit in real terms, which was then divided by IFS line 99b.p. (interpolated) to obtain the domestic credit/GDP ratio. Monthly real GDP was interpolated from annual data.
3. Domestic Real Interest Rate: Deposit rate (IFS line 60) deflated using consumer prices (IFS line 64). Monthly rates expressed in percentage points. In levels.
4. “Excess” M1 balances: M1 (IFS line 34) deflated by consumer prices (IFS line 64) less an estimated demand for money. The demand for real balances is determined by real GDP (interpolated IFS line 99b.p), domestic consumer price inflation, and a time trend. Domestic inflation was used in lieu of nominal interest rates, as market-determined interest rates were not available during the entire sample for a number of countries; the time trend is motivated by its role as a proxy for financial innovation and/or currency substitution. In levels.
5. M2/Reserves: IFS lines 34 plus 35 converted into dollars (using IFS line 11) divided by IFS line 1L.d.
6. Bank Deposits: IFS line 24 plus 25 deflated by consumer prices (IFS line 64).
7. Exports: IFS line 70.
8. Imports: IFS line 71.
9. Terms of Trade: The unit value of exports (IFS line 74) over the unit value of imports (IFS line 75). For those developing countries where import unit values (or import price indices) were not available, an index of prices of manufactured exports from industrial countries to developing countries was used.

10. The Real Exchange Rate: The real exchange rate index is derived from a nominal exchange rate index, adjusted for relative consumer prices (IFS line 64). The measure is defined as the relative price of foreign goods (in domestic currency) to the price of domestic goods. The nominal exchange rate index is a weighted average of the exchange rates of the nineteen OECD countries with weights equal to the country trade shares with the OECD countries. Since not all real appreciations reflect disequilibrium phenomena, we focus on deviations of the real exchange rate from trend. In levels.

11. Reserves: IFS line IL.d.

12. Output: For most countries, the measure of output used is industrial production (IFS line 66). However, for some countries, (the commodity exporters) an index of output of primary commodities is used (IFS lines 66aa), if industrial production is not available.

13. Stock returns: IFC global indices are used for all emerging markets: for industrial countries the quotes from the main boards are used. All stock prices are in US dollars.

14. Short-term Foreign Debt: Liabilities of domestic residents to BIS reporting banks with maturities up to one year divided by total liabilities of domestic residents to BIS reporting banks, interpolated from semi-annual data. The Maturity, Sectoral, and Nationality Distribution of International Bank Lending, Bank for International Settlements.

16. World Real Interest Rate: US deposit rate (IFS line 60) deflated using consumer prices (IFS line 64). Monthly rates expressed in percentage points. In levels.

17. Fiscal Deficit: The ratio of fiscal deficit (IFS line 80) deflated by consumer prices (IFS line 64) to GDP (IFS line 99b.p) interpolated.
